Overview

In this Homework Assignment, we explore various numerical optimization methods through the lens of the Black-Scholes-Merton Option pricing model[1]. Using this, we calculate and explore the implied volatility of options for various assets traded on the market. Furthermore, we also explore numeric methods of differential calculation to compute the Greeks of these candidate options. Finally, we explore numeric integration and the behavior of various quadrature methods.

Unless otherwise stated, the following shorthand notation is used to distinguish between dates:

- **DATA1** - Wednesday, February 6 2019 (*2/6/19*);
- **DATA2** - Thursday, February 7 2019 (*2/7/19*).

The content of this Homework Assignment is divided into three sections; the first discusses data gathering, formatting, and a discussion of the assets being examined. The second contains data analysis, and an exploration of implied volatility through the Black-Scholes-Merton pricing framework and related computations. Finally, the third section discusses numerical integration and the convergence of various quadrature rules.

See Appendix C for specific question implementations, and the project GitHub repository[2] for full source code of the `fe621` *Python package.*

Contents

1 Data Overview

1.1 Asset Descriptions

1.1.1 *SPY* - SPDR S&P 500 ETF[3]

The S&P 500 (i.e. *Standard & Poor's 500*) is a stock market index tracking the 500 largest companies on the American Stock Exchange by Market Capitalization. In this case, the market capitalization is defined as the number of outstanding shares, multiplied by the current share price. A stock market index is designed to be a metric that can be used by market observers as a benchmark to gauge the relative health of the stock market, by analyzing the aggregate performance of its largest components.

However, this index is not the same as the *SPY* ETF. An ETF (*Exchange Traded Fund*) is a basket of stocks that is designed to track a specific index or benchmark. That is, it provides investors with exposure to a index or benchmark, without having to own all of the underlying assets that constitute a composite ETF. In addition to higher liquidity, this type of investment also provides lower transaction costs and required minimum investment to gain exposure to a given index or benchmark. It is traded on an exchange, akin to a typical traded asset.

1.1.2 *VIX* - CBOE Volatility Index[4]

The CBOE (*Chicago Board Options Exchange*) volatility index, *VIX* is an exchange traded product (*ETP*) designed to give investors exposure to the market's expectation of 30-day volatility. It is priced using a large set of implied volatility of put and call options on the S&P 500 index to gauge investor sentiment. Typically, the price of the VIX has an inverse relationship to the price of the S&P 500 index. Similar to an ETF, an ETP is also traded on an exchange as a typical traded asset.

1.2 Data Gathering

For the assignment, we downloaded monthly options on *Amazon Inc.* (ticker: AMZN) and *S&P 500 ETF* (ticker: SPY) at various strike prices for the following dates:

- *02/15/19* - Friday, February 15 2019;
- *03/15/19* - Friday, March 15 2019;
- *04/18/19* - Thursday, April 18 2019.

A wide variety of option strike prices were considered, with the following ranges:

- *AMZN* - \$1555 to \$1725 in increments of \$5 (35 strike prices);
- *SPY* - \$256 to \$284 in increments of \$1 (29 strike prices).

Intra-day minute closing price data was gathered for both put and call options with expiration dates and strike prices detailed above. This intra-day data was gathered for the trading day *2/6/19* (February 6 2019; **DATA1**). Additionally, intra-day minute closing price data was also downloaded for each of the underlying assets. This data was downloaded for both *2/6/19* (February 6 2019; **DATA1**), and *2/7/19* (February 7 2019; **DATA2**).

3. State Street Global Advisors 2019
4. CBOE (Chicago Board Options Exchange) 2019

This data detailed above was gathered utilizing *Rblpapi*[5], which provides an R interface to data on the Bloomberg Terminal[6]. The data download was automated, and corresponding intra-day prices for each of the options were output to individual files. The source code for this implementation is available in Appendix C.1.1.

Furthermore, as a proxy for the *risk-free rate*, we chose to utilize the effective Federal Funds Rate (FFR). This is the interest rate at which depository institutions in the United States lend reserve balances to other depository institutions overnight. This data was gathered for both dates, and correspond to **DATA1** and **DATA2**. The effective FFR is published daily by the US Federal Reserve Board of Governors, and are expressed as yields per annum.[7]

1.2.1 Data Cleaning

For easier programmatic access, the data was placed in a hierarchical structure, corresponding to the **DATA1**, **DATA2** data division. Each of the option and asset prices for the corresponding days were placed in the requisite sub-folders. This directory structure is reproduced below.

```
data
├── DATA1
│   ├── AMZN
│   ├── SPY
│   └── VIX
└── DATA2
    ├── AMZN
    ├── SPY
    └── VIX

8 directories
```

Option price filenames were changed to OOC format option names, discussed further below. This was done utilizing a cleaning script, written in Python. This script employs utility functions from the `fe621` Python package[8].

1.3 Option Naming Convention

A modern convention for naming option contracts was proposed by the Options Clearing Commission (OCC) in 2008[9], and adopted in 2010. The OCC is an organization that acts as both the issuer and guarantor for option and future contracts. The OCC is governed by the Securities and Exchange Commission (SEC) and the Commodities Futures Trading Commission (CFTC). The current convention for option naming is best explained by example.

Consider the option code, *AMZN190215C01960000*. This corresponds to a **Call Option** on **Amazon Inc. (AMZN)**, with a strike price of **$1960.00** and an expiration date of **2/15/19** (February 15 2019).

The methodology of this nomenclature is explained in detail below:

5. Armstrong et al. 2018
6. Bloomberg L.P. 2019
7. Board of Governors of the Federal Reserve System 2019
8. Weerawarana 2019
9. Options Symbology Initiative Working Group 2008

AMZN190215C01960000

- **AMZN** - Ticker of the company (arbitrary length; always first sequence of characters)
- **19** - Expiration year of the contract (shortened to two digits, i.e. 2019 $\rightarrow$ 19)
- **02** - Expiration month of the contract
- **15** - Expiration day of the contract
- **C** - Type of option (C for call, P for put)
- **01960** - Dollar component of strike price (in $; always 5 digits)
- **000** - $\frac{1}{1000}^{\text{th}}$ Dollar component of strike price (in $\frac{1}{1000}$$; always 3 digits)

Similarly, the following option code corresponds to a **Put Option** on **SPDR S&P 500 ETF (SPY)**, with a strike price of **$287.50** and an expiration date of **3/15/19** (March 15 2019):

SPY190315P00287500

Finally, the following option code corresponds to a **Call Option** on **CBOE Volatility Index (VIX)**, with a strike price of **$16.35** and an expiration date of **4/18/19** (February 18 2019):

VIX190418C00016350

2 Data Analysis

Note: All Python scripts reproduced in this section are extracted from the `fe621`[10] *package created for this class.*

2.1 Black-Scholes Model

With the probabilities d_1 and d_2 defined as:

$$d_1 = \frac{\log\left(\frac{S_t}{K}\right) + \left(r + \frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}$$

$$d_2 = d_1 - \sigma\sqrt{T-t}$$

$$\Phi(x) = \int_{-\infty}^{x} \phi(z)dz = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} e^{\frac{-z^2}{2}} dz$$

```python
from typing import Tuple

import numpy as np

def computeD1D2(current: float, volatility: float, ttm: float, strike: float,
                rf: float) -> Tuple[float, float]:
    """Helper function to compute the risk-adjusted priors of exercising the
    option contract, and keeping the underlying asset. This is used in the
    computation of both the Call and Put options in the
    Black-Scholes-Merton framework.

    Arguments:
        current {float} -- Current price of the underlying asset.
        volatility {float} -- Volatility of the underlying asset price.
        ttm {float} -- Time to expiration (in years).
        strike {float} -- Strike price of the option contract.
        rf {float} -- Risk-free rate (annual).

    Returns:
        Tuple[float, float] -- Tuple with d1, and d2 respectively.
    """

    d1 = (np.log(current / strike) + (rf + ((volatility ** 2) / 2)) * ttm) \
        / (volatility * np.sqrt(ttm))
    d2 = d1 - (volatility * np.sqrt(ttm))

    return (d1, d2)
```

../fe621/black_scholes/util.py

10. Weerawarana 2019

Note: **The following assumes the dividend rate, $q = 0$.**

2.1.1 Put Option

The Black-Scholes Option price for a European Put ($P(S_t)$) option is defined as:

$$P(S_t) = Ke^{-r(T-t)}\Phi(-d_2) - S_t\Phi(-d_1)$$

```python
from .util import computeD1D2

from scipy.stats import norm
import numpy as np

def blackScholesPut(current: float, volatility: float, ttm: float,
                    strike: float, rf: float) -> float:
    """Function to compute the Black-Scholes-Merton price of a European Put
    Option, parameterized by the current underlying asset price, volatility,
    time to expiration, strike price, and risk-free rate.

    Arguments:
        current {float} -- Current price of the underlying asset.
        volatility {float} -- Volatility of the underlying asset price.
        ttm {float} -- Time to expiration (in years).
        strike {float} -- Strike price of the option contract.
        rf {float} -- Risk-free rate (annual).

    Returns:
        float -- Price of a European Put Option contract.
    """

    d1, d2 = computeD1D2(current, volatility, ttm, strike, rf)

    put = (strike * np.exp(-1 * rf * ttm) * norm.cdf(-1 * d2)) \
        - (strike * norm.cdf(-1 * d1))

    return put
```

../fe621/black_scholes/put.py

2.1.2 Call Option

The Black-Scholes Option price for a European Call ($C(S_t)$) option is defined as:

$$C(S_t) = S_t\Phi(d_1) - Ke^{-r(T-t)}\Phi(d_2)$$

```python
from .util import computeD1D2

from scipy.stats import norm
import numpy as np

def blackScholesCall(current: float, volatility: float, ttm: float,
                     strike: float, rf: float) -> float:
    """Function to compute the Black-Scholes-Merton price of a European Call
```

```
    Option, parameterized by the current underlying asset price, volatility,
    time to expiration, strike price, and risk-free rate.

    Arguments:
        current {float} -- Current price of the underlying asset.
        volatility {float} -- Volatility of the underlying asset price.
        ttm {float} -- Time to expiration (in years).
        strike {float} -- Strike price of the option contract.
        rf {float} -- Risk-free rate (annual).

    Returns:
        float -- Price of a European Call Option contract.
    """

    d1, d2 = computeD1D2(current, volatility, ttm, strike, rf)

    call = (current * norm.cdf(d1)) \
        - (strike * np.exp(-1 * rf * ttm) * norm.cdf(d2))

    return call
```

../fe621/black_scholes/call.py

2.1.3 Put-Call Parity

The relationship between the price of a Call and Put option is governed by Put-Call parity:

$$P(S_t) = C(S_t) - S_t + Ke^{-r(T-t)}$$

```
import numpy as np

def call(put: float, current: float, strike: float, ttm: float,
         rf: float) -> float:
    """Function to compute the price of a European Call option contract from a
    European Put option contract price using Put-Call parity.

    Arguments:
        put {float} -- Price of the put option.
        current {float} -- Current price of the underlying asset.
        strike {float} -- Strike price of the option contract.
        ttm {float} -- Time to expiration (in years).
        rf {float} -- Risk-free rate (annual).

    Returns:
        float -- Price of a European Call Option contract.
    """

    return put + current - (strike * np.exp(-1 * rf * ttm))

def put(call: float, current: float, strike: float, ttm: float,
        rf: float) -> float:
    """Function to compute the price of a European Put option contract from a
    European Call option contract price using Put-Call parity.

    Arguments:
        call {float} -- Price of the call option.
        current {float} -- Current price of the underlying asset.
```

```
31          strike {float} -- Strike price of the option contract.
32          ttm {float} -- Time to expiration (in years).
33          rf {float} -- Risk-free rate (annual).
34
35      Returns:
36          float -- Price of a European Put Option contract.
37      """
38
39      return call - current + (strike * np.exp(-1 * rf * ttm))
```

../fe621/black_scholes/parity.py

2.1.4 The Greeks

The Greeks are the quantities representing the sensitivity of the price of a derivative with respect to changes in the underlying parameters. The following formulas are implemented to calculate each of the Greeks using the Black-Scholes option pricing formula. These formulas are derived in full in (Stefanica 2011) and (Weerawarana 2016).

Note: **The following assumes the dividend rate,** $q = 0$**.**

Delta

The Delta (Δ) of an option is the first derivative of an option with respect to the price of the underlying asset at time t, S_t.

$$\Delta(C) = \frac{\partial C(S_t)}{\partial S_t} = \Phi(d_1)$$

Gamma

The Gamma (Γ) of an option is the second derivative of an option with respect to the price of the underlying asset at time t, S_t.

$$\Gamma(C) = \frac{\partial^2 C(S_t)}{\partial S_t^2} = \frac{\phi(d_1)}{S_t \sigma \sqrt{T - t}}$$

Vega

The Vega (ν) of an option is the first derivative of an option with respect to the volatility of the underlying asset at time t, σ.

$$\nu(C) = \nu(P) = \frac{\partial C(S_t)}{\partial \sigma} = S_t \sqrt{T - t}\, \phi(d_1)$$

```
1  from .util import computeD1D2
2
3  from scipy.stats import norm
4
5  import numpy as np
6
7
8  def callDelta(current: float, volatility: float, ttm: float, strike: float,

    Returns:
        float -- Vega of a European Option contract.
    """

    d1, _ = computeD1D2(current, volatility, ttm, strike, rf)

    return current * np.sqrt(ttm) * norm.pdf(d1)
```

../fe621/black_scholes/greeks.py

2.2 Numeric Optimization

2.2.1 Bisection Method

In this section, we implement the Bisection optimization method. The bisection algorithm is outlined in Algorithm 1. The algorithm is implemented recursively.

Algorithm 1: Bisection Algorithm

Input: Input function, f to be optimized; must have sign change. Search space start and stop points, a and b. Tolerance level, ϵ.
Output: Point $x^* \in [a, b]$ where $f(x^*) = 0$.
Let midpoint $= m$;
repeat
  $m = \frac{a+b}{2}$;
  if $f(a) \times f(mid) < 0$ **then**
    $b = m$
  end
  if $f(b) \times f(mid) < 0$ **then**
    $a = m$
  end
until $(b - a) < \epsilon$;
return $\frac{a+b}{2}$;

```python
from typing import Callable
import numpy as np

def bisectionSolver(f: Callable, a: float, b: float,
                    tol: float=10e-6) -> float:
    """Bisection method solver, implemented using recursion.

    Arguments:
        f {Callable} -- Function to be optimized.
        a {float} -- Lower bound.
        b {float} -- Upper bound.

    Keyword Arguments:
        tol {float} -- Solution tolerance (default: {10e-6}).

    Raises:
        Exception -- Raised if no solution is found.

    Returns:
        float -- Solution to the function s.t. f(x) = 0.
    """

    # Compute midpoint
    mid = (a + b) / 2

    # Check if estimate is within tolerance
    if (b - a) < tol:
        return mid

    # Evaluate function at midpoint
    f_mid = f(mid)
```

```
33
34      # Check position of estimate, move point and re-evaluate
35      if (f(a) * f_mid) < 0:
36          return bisectionSolver(f=f, a=a, b=mid)
37      elif (f(b) * f_mid) < 0:
38          return bisectionSolver(f=f, a=mid, b=b)
39      else:
40          raise Exception("No solution found.")
```

../fe621/optimization/bisection.py

2.2.2 Newton Method

In this section, we implement the Newton optimization method. The Newton method algorithm is outlined in Algorithm 2.[11] The algorithm is implemented recursively.

Algorithm 2: Newton's Method

Input: A differentiable function $f : \mathbb{R}^a \to \mathbb{R}^b \, \forall \, a, b \in \mathbb{N}_{>0}$. Starting guess for the root x_0. Tolerance level, ϵ.
Output: $x^* \in \mathbb{R}^a$, such that $f(x^*) = 0$
$k = 1$;
repeat
  $x_{k+1} = x_k - \frac{f(x_k)}{f'(x_k)}$;
  $k = k + 1$
until $|x_k - x_{k-1}| < \epsilon$;
return x_{k+1};

```
1  from typing import Callable
2  import numpy as np
3
4
5  def newtonSolver(f: Callable, f_prime: Callable, guess: float,
6                   tol: float=10e-6, prev: float=0) -> float:
7      """Newton method solver for 1 dimension, implemented recursively.
8
9      Arguments:
10         f {Callable} -- Objective function (must have zero root).
11         f_prime {Callable} -- First derivative of objective with respect to
12                               the decision variable.
13         guess {float} -- Guess for the decision variable.
14
15     Keyword Arguments:
16         tol {float} -- Tolerance level (default: {10e-6}).
17         prev {float} -- Guess from previous iteration (for convergence check).
18
19     Returns:
20         float -- Solution to the function s.t. f(x) = 0.
21     """
22
23     # Assigning current guess to x_old
24     x_old = guess
25
```

11. Stefanica 2011

```
26      # Checking if decision variable changed by less than tolerance level
27      if np.abs(x_old - prev) < tol:
28          return x_old
29      else:
30          # Compute new estimate for x
31          x_new = x_old - (f(x_old) / f_prime(x_old))
32          return newtonSolver(f=f, f_prime=f_prime, guess=x_new,
33                              tol=tol, prev=x_old)
```

../fe621/optimization/newton.py

2.2.3 Convergence Comparison

Here, we compare the performance of each of the optimization methods described above, the Bisection method and Newton method. This was done by computing the average daily implied volatility on the complete SPY option chain in the dataset.

The average daily implied volatility is computed by first calculating the implied volatility by-minute. Then, the mean of these minute-level implied volatilities is computed and is treated as the average daily implied volatility of the given option. For this comparison, the tolerance level of each of the termination conditions was set to 1×10^{-4}.

	Newton Method	Bisection Method
Number of Input Options	165.0	165.0
Number of Output Options	164.0	164.0
Number of Dropped Options	1.0	1.0
Time Elapsed for Computation (s)	2423.1484701633453	2406.0394039154053
Average Time per Option (s)	14.685748304020274	14.582056993426699

Table 1: Convergence comparison of average daily implied volatility computation on the SPY option chain using the Bisection and Newton optimization methods.

The time elapsed for these computations, and other related statistics under each of the two optimization methods are presented in Table 1.

Despite having a theoretical quadratic convergence rate, Newton's method results in slower performance compared to the Bisection method. This is evident from both the total time elapsed, and the average time per operation (computed to include dropped option computations for consistency).

This can be attributed to the fact that some of the minute-level implied volatility optimizations do not have solutions. The Bisection method reaches a state of "no solution" faster than Newton's method, as it employs a technique of reducing the possible range of the solution. This converging search space would suggest it discovers a state of "no solution" faster than the unbounded search space of the Newton method. In principle - on the condition that the existence of a solution is guaranteed - the Newton method will converge faster than the Bisection method, given a reasonable initial guess.

2.3 Implied Volatility

In this section, we utilize the functions and data described above to calculate the average implied volatility of each of the option chains. This was done for the entire dataset using the Bisection Method. Additionally, we also discuss the differences in average daily implied volatility between *in-the-money* and *out-of-the-money* options.

2.3.1 Average Daily Implied Volatility

Average daily implied volatility was computed for each option, across all strike prices and expiration dates, for both SPY and AMZN option chains. This optimization on the aggregate dataset was completed using the Bisection Method.

This was done by first computing the implied volatility for each minute, solving for some σ such that $(C(S_t)|_\sigma - P = 0)$ or $(P(S_t)|_\sigma - P = 0)$ for a call or put option respectively. Then, the mean of each of these implied volatilities was computed to obtain the daily average implied volatility for an option with a given strike price and expiration date. For this comparison, the tolerance level of each of the termination conditions was set to 1×10^{-7}.

The complete dataset of average daily implied volatility is reproduced for the complete option chains on SPY in Appendix A.1 and AMZN in Appendix A.2.

2.4 Implied Volatility Analysis

We also compared the average daily implied volatility of options *in-the-money*, and *out-of-the-money*. For this comparison, we defined the ratio of *money-ness* to be $\pm 5\%$ of the current underlying asset price, where options within the range are *in-the-money*, and *out-of-the-money* otherwise. This comparison data is presented in Table 2.

	SPY	AMZN
In-the-money Options Average Daily Implied Vol	0.15739310934145576	0.29781477676343643
Out-of-the-money Options Average Daily Implied Vol	0.16631389625540363	0.3189350623328305

Table 2: Comparison of *in-the-money* and *out-of-the-money* options through the lens of their average daily implied volatility.

2.5 Volatility Plots

In this section, we explore the visual relationship between the computed average daily implied volatility (see Section 2.3.1), the strike price, and the expiration date of the options. The source code for this question is reproduced in Appendix C.2.4.

2.5.1 Volatility Smile

The Volatility Smile is the graph of the relationship between the strike price and the average daily implied volatility of the option:

$$\hat{\sigma} = \hat{f}(K)$$

The various options (of the same type and underlying asset) are graphed on the same axes, and different expiration dates are displayed in different colors. The Volatility Smile is plotted for both put and call options on both SPY and AMZN in Figure 1.

2.5.2 Volatility Surface

The Volatility Surface is the graph of the relationship between the strike price, the time to maturity, and the average daily implied volatility of the option:

$$\hat{\sigma} = \hat{f}(K, \sqrt{T - t})$$

The various options (of the same type and underlying asset) are graphed on the same axes. The Volatility Surface is plotted for both put and call options on both SPY and AMZN in Figure 2.

2.6 The Greeks

In this section, we compute the Greeks for the options. To do this, we employ the estimate of the average daily implied volatility (see Section 2.3.1). We compute the Greeks using both the analytical formula (see Section 2.1.4), and by estimation of the derivatives using the central finite difference Method.

2.6.1 Central Finite Difference Method

The central finite difference method is a framework for computing the numerical derivative of a three times differentiable function in an interval around the point a, f. Then, numerical approximations for the first and second derivatives are[12]:

3 Numerical Integration

3.1 Quadrature Methods

In this section, we implement the *Trapezoidal Rule* and *Simpson's Rule* quadrature methods.

$$\text{Let data} = \boldsymbol{x}$$
$$\text{Let } i^{\text{th}} \text{ element of } \boldsymbol{x} = x_i$$

3.1.1 Trapezoidal Rule

$$\text{Let Trapezoidal rule approximation} = T_N(f)$$
$$\Rightarrow T_N(f) = \sum_{i=1}^{N} \left[\left(\frac{f(x_{i-1}) + f(x_i)}{2} \right) \times h \right]$$
$$\Rightarrow h \times \sum_{i=1}^{N} \left[\frac{f(x_{i-1}) + f(x_i)}{2} \right] = h \times \left(\frac{1}{2} f(x_0) + f(x_1) + \cdots + f(x_{N-1} + \frac{1}{2} f(x_N)) \right)$$
$$\therefore T_N(f) = hf(\boldsymbol{x}) - \frac{h}{2}(f(x_0) + f(x_N))$$

```python
from typing import Callable
import numpy as np

def trapezoidalRule(f: Callable, N: float, start: float=-1e6,
                    stop: float=1e6) -> float:
    """Function to approximate the numeric integral of a function, f, using
    the Trapezoidal rule.

    Arguments:
        f {Callable} -- Function who's integral is to be estimated.
        N {int} -- Number of nodes to consider.

    Keyword Arguments:
        start {float} -- Starting point (default: {-1e6}).
        stop {float} -- Stopping point (default: {1e6}).

    Returns:
        float -- Approximation of the area under the function.
    """

    # Building values for approximation, and getting step size
    x, h = np.linspace(start=start, stop=stop, num=N, retstep=True)

    # Estimating area using trapezoidal rule, return
    return np.sum((h * f(x))) - ((h / 2) * (f(start) + f(stop)))
```

../fe621/numerical_integration/trapezoidal.py

3.1.2 Simpson's Rule

The following equation is derived in full in (Florescu 2019).

$$\text{Let Simpson's rule approximation} = S_N(f)$$

$$\Rightarrow S_N(f) \approx \frac{h}{6} \times \sum_{i=1}^{N} \left[f(x_{i-1}) + 4f\left(\frac{x_{i-1} + x_i}{2} \right) + f(x_i) \right]$$

$$= \frac{h}{6} \left(\sum_{i=1}^{N} [f(x_{i-1}) + f(x_i)] + 4 \times \sum_{i=1}^{N} \left[f\left(\frac{x_{i-1} + x_i}{2} \right) \right] \right)$$

$$\text{Note that } \left(\frac{x_{i-1} + x_i}{2} \right) \text{ is the midpoint between the points in } \boldsymbol{x}.$$

$$\text{Let the above} = \boldsymbol{x}_{\text{mid}}$$

$$\therefore S_N(f) \approx \frac{h}{6} \left(2f(\boldsymbol{x}) - (f(x_0) + f(x_N)) + 4f(\boldsymbol{x}_{\text{mid}}) \right)$$

```python
from typing import Callable
import numpy as np

def simpsonsRule(f: Callable, N: float, start: float=-1e6,
                 stop: float=1e6) -> float:
    """Function to approximate the numeric integral of a function, f, using
    Simpson's rule.

    Arguments:
        f {Callable} -- Function for which the integral is to be estimated.
        N {float} -- Number of nodes to consider.

    Keyword Arguments:
        start {float} -- Starting point (default: {-1e6}).
        stop {float} -- Stopping point (default: {1e6}).

    Returns:
        float -- Approximation of the area under the function.
    """

    # Building values for approximation, and getting step size
    x, h = np.linspace(start=start, stop=stop, num=N, retstep=True)

    # Computing midpoints
    x_mid = np.array([(x[i - 1] + x[i]) / 2 for i in range(1, N)])

    # Estimating using Simpson's rule
    area = np.sum(2 * f(x)) - (f(start) + f(stop)) + (4 * np.sum(f(x_mid)))

    # Scaling area
    area *= (h / 6)

    return area
```

../fe621/numerical_integration/simpsons.py

3.2 Truncation Error Analysis

To examine the behavior of each of the quadrature methods described above, we approximate the integral of the following function:

$$f(x) = \begin{cases} \frac{\sin(x)}{x}, & \text{for } x \neq 0, \\ 1, & \text{for } x = 0. \end{cases}$$

We parameterize the start and stop points of the quadrature methods with a variable a, such that start $= -a$ and stop $= a$. Furthermore, we define the number of segments with variable N.

Let approximation with parameters a and $N = I_{N,a}$

It is know analytically that the value of the integral $\int_{\infty}^{\infty} f(x)dx = \pi$. We evaluate the performance of each of the quadrature methods with various values of a and N. Then, we compute the *truncation error* of the approximation, defined as:

Truncation error for approximation with parameters a and $N = |I_{N,a} - \pi|$

	N = 1000	N = 10000	N = 100000	N = 1000000	N = 10000000
a = 100	1.70837393e-02	7.23666391e-04	6.28030676e+00	6.28753820e+00	8.02007982e-04
a = 1000	1.71411414e-02	1.12266273e-03	1.22268346e-04	6.28287768e+00	6.28285876e+00
a = 10000	1.71417140e-02	1.12637221e-03	1.89801996e-04	1.28334824e-05	6.28321420e+00
a = 100000	1.71417198e-02	1.12640928e-03	1.90430835e-04	1.99205411e-05	1.20297055e-06
a = 1000000	1.71417198e-02	1.12640965e-03	1.90437119e-04	1.99865427e-05	1.86725626e-06

Table 3: Trapezoidal quadrature rule truncation error for varying values of a and N.

	N = 1000	N = 10000	N = 100000	N = 1000000	N = 10000000
a = 100	1.71417296e-02	1.13348528e-03	1.04706334e+01	1.27753456e+02	1.33203419e+03
a = 1000	1.71417198e-02	1.12641028e-03	1.91636193e-04	1.04718335e+01	1.27758461e+02
a = 10000	1.71417198e-02	1.12640965e-03	1.90437288e-04	2.01130216e-05	1.04719888e+01
a = 100000	1.71417198e-02	1.12640965e-03	1.90437182e-04	1.99872209e-05	1.88530816e-06
a = 1000000	1.71417198e-02	1.12640965e-03	1.90437182e-04	1.99872089e-05	1.87350648e-06

Table 4: Simpsons quadrature rule truncation error for varying values of a and N.

Table 3 and Table 4 report the truncation error for the Trapezoidal and Simpson's quadrature rules, respectively. The script used to produce this table is reproduced in Appendix C.3.1. Variations of N and a are explores in increasing powers of 10, with a progressing from 100 to 1,000,000, and N from 1,000 to 10,000,000.

It is evident from Table 3 that the Trapezoidal quadrature rule performs relatively well across all values of a, even at relatively low values of N. Compared to Simpson's quadrature rule truncation error (Table 4), the Trapezoidal quadrature rule also performs relatively better with larger values of N, and small values of a.

A potential explanation of this may be the interpolating behavior of the Simpson's quadrature rule. The function $\frac{sin(x)}{x}$ is significantly more linear than quadratic in small intervals, and thus the quadratic

interpolating behavior of the Simpson's quadrature rule is a poor approximation heuristic for the function with low values of a.

Finally, it can be observed that both quadrature rule approximations converge commensurately as the values of a and N increase. However, it is clear that the Trapezoidal quadrature rule approximation converges at a faster rate than the Simpson's quadrature rule approximation with increasing values of a and N.

3.3 Convergence Analysis

Typically, the true value of the objective integral is unknown. In this case, we would evaluate the rate of change of the objective function (i.e. convergence) computation with respect to the number of segments, N. We assign an arbitrary convergence criteria, ϵ to test the convergence with progressively increasing (in powers of 10) values of N.

$$\text{Let approximation with parameter } N = I_N$$
$$\text{Repeat while: } |I_N - I_{N_{\text{old}}}| > \epsilon$$

We evaluate the number of iterations required for a convergence level of $\epsilon = 10^{-3}$ for the Trapezoidal and Simpson's quadrature rules. The output of this evaluation is reproduced in Table 5. The solution source code for this analysis is reproduced in Appendix C.3.2. The `fe-621` package[13] sub-module used in this analysis is presented below.

```python
from typing import Callable, Tuple
import numpy as np

def convergenceApproximation(f: Callable, rule: Callable, epsilon: float=1e-3,
                             start: float=-1e6, stop: float=1e6) \
                            -> Tuple[float, int]:
    """Function to approximate the numeric integral of a function, f, using
    a given quadrature rule and a tolerance level epsilon.

    Arguments:
        f {Callable} -- Function for which the integral is to be estimated.
        rule {Callable} -- Function to be used to approximate area. Must take
                           positional arguments f, N, start and stop.

    Keyword Arguments:
        epsilon {float} -- Tolerance level (default: {1e-3}).
        start {float} -- Starting point (default: {-1e6}).
        stop {float} -- Stopping point (default: {1e6}).

    Returns:
        Tuple[float, int] -- Approximation of the area under the function
                             and the number of segments (area, segments).
    """

    # Flags
    area_old = 0
    area_new = 1
    N = 1

    while (np.abs(area_new - area_old) > epsilon):
        # Set new area to old area
        area_old = area_new
```

13. Weerawarana 2019

```
34
35          # Increase N by powers of 10
36          N *= 10
37
38          # Computing area with given parameters
39          area_new = rule(f=f, N=N, start=start, stop=stop)
40
41          # Log
42          print('On iteration {0} method {1} convergence {2} val {3}'.format(
43              N, str(rule),
44              '{:.5e}'.format(np.abs(area_new - area_old)),
45              area_new))
46
47      # Return final area and number of segments
48      return (area_new, N)
```

../fe621/numerical_integration/convergence.py

	Estimated Area	Segments
Trapezoidal Rule	3.14162154e+00	1.00000000e+05
Simpson's Rule	3.14159078e+00	1.00000000e+07

Table 5: Analysis of segments required for convergence under the Trapezoidal and Simpson's quadrature rules.

Analyzing the results in Table 5, it is evident that the number of segments required for convergence under the Trapezoidal quadrature rule is significantly less than that required under Simpson's quadrature rule. This difference is significant, with the Trapezoidal quadrature rule requiring segments two orders of magnitude less than Simpson's quadrature rule for convergence. These behavior is in agreement with the previous analysis of convergence with respect to varying values of N and a, explored in Section 3.2.

3.3.1 Arbitrary Function

Additionally, we also evaluate each quadrature rule with respect to the number of segments required for convergence with an additional arbitrary integral:

$$g(x) = 1 + e^{-x^2} \cos\left(8x^{\frac{2}{3}}\right)$$

$$\int_0^2 g(x)\, dx$$

	Estimated Area	Segments
Trapezoidal Rule	1.95879798e+00	1.00000000e+04
Simpson's Rule	1.95879793e+00	1.00000000e+03

Table 6: Analysis of segments required for convergence of an arbitrary integral under the Trapezoidal and Simpson's quadrature rules.

The estimates and segments required for convergence for the integral $\int_0^2 g(x)\, dx$ are presented in Table 6. The source code for this analysis is reproduced in Appendix C.3.3.

C Solution Source Code

C.1 Question 1 Implementation

C.1.1 Bloomberg Terminal Data Download

```
library("Rblpapi")

# Connect to Bloomberg Terminal backend service
blpConnect(host = "localhost", port = 8194)

#----------------------------------
# Data Download Functionality
#----------------------------------

getPrice <- function(security, startTime, endTime, timeZone) {
  # Downloads and returns the closing price of a given security
  # for each minute in the trading day.
  #
  # Args:
  #   security: Name of the security to be downloaded.
  #   startTime: Datetime object with the start time.
  #   endTime: Datetime object with the end time.
  #   timeZone: Time zone of the target start and end times.
  #
  # Returns:
  #   DataFrame with the closing price for each minute in the
  #   trading day.

  # Getting price data
  data <- getBars(security = security, barInterval = 1,
                  startTime = startTime, endTime = endTime,
                  tz = timeZone)

  # Isolate time and closing price
  data <- data[c("times", "close")]

  # Rename columns
  colnames(data) <- c("Dates", "Close")

  # Return
  data
}

createOptionName <- function(security, dates, prices, type, suffix) {
  # Creates the Bloomberg-standard option name, given a security, date, price,
  # option type and suffix.
  #
  # Args:
  #   security: Name of the security to be included in the option price.
  #   dates: Dates to be included in option name.
  #   prices: Prices to be included in the option name.
  #   type: Type of the option ("C" or "P").
  #   suffix: Suffix for option name (typically "Index" or "Equity").
  #
  # Returns:
  #   Vector of Bloomberg-compatible option names.
```

```
55
56    # Empty vector to store names
57    names <- c()
58
