## Homework Assignment 1

## Rukmal Weerawarana

FE~621: Computational Methods in Finance

Instructor: Ionut Florescu

2/20/2019

rweerawa@stevens.edu | 104-307-27 Department of Financial Engineering Stevens Institute of Technology

## Overview

In this Homework Assignment, we explore various numerical optimization methods through the lens of the Black-Scholes-Merton Option pricing model<sup>1</sup>. Using this, we calculate and explore the implied volatility of options for various assets traded on the market. Furthermore, we also explore numeric methods of differential calculation to compute the Greeks of these candidate options. Finally, we explore numeric integration and the behavior of various quadrature methods.

Unless otherwise stated, the following shorthand notation is used to distinguish between dates:

- **DATA1** Wednesday, February 6 2019 (2/6/19);
- **DATA2** Thursday, February 7 2019 (2/7/19).

The content of this Homework Assignment is divided into three sections; the first discusses data gathering, formatting, and a discussion of the assets being examined. The second contains data analysis, and an exploration of implied volatility through the Black-Scholes-Merton pricing framework and related computations. Finally, the third section discusses numerical integration and the convergence of various quadrature rules.

See Appendix D for specific question implementations, and the project GitHub repository<sup>2</sup> for full source code of the fe621 Python package.

## 1 Data Overview

## 1.1 Asset Descriptions

#### 1.1.1 SPY - SPDR S&P 500 ETF<sup>3</sup>

The S&P 500 (i.e. Standard & Poor's 500) is a stock market index tracking the 500 largest companies on the American Stock Exchange by Market Capitalization. In this case, the market capitalization is defined as the number of outstanding shares, multiplied by the current share price. A stock market index is designed to be a metric that can be used by market observers as a benchmark to gauge the relative health of the stock market, by analyzing the aggregate performance of its largest components.

However, this index is not the same as the SPY ETF. An ETF (Exchange Traded Fund) is a basket of stocks that is designed to track a specific index or benchmark. That is, it provides investors with exposure to a index or benchmark, without having to own all of the underlying assets that constitute a composite ETF. In addition to higher liquidity, this type of investment also provides lower transaction costs and required minimum investment to gain exposure to a given index or benchmark. It is traded on an exchange, akin to a typical traded asset.

### 1.1.2 VIX - CBOE Volatility Index<sup>4</sup>

The CBOE (*Chicago Board Options Exchange*) volatility index, *VIX* is an exchange traded product (*ETP*) designed to give investors exposure to the market's expectation of 30-day volatility. It is priced using a large set of implied volatility of put and call options on the S&P 500 index to gauge investor sentiment. Typically, the price of the VIX has an inverse relationship to the price of the S&P 500 index. Similar to an ETF, an ETP is also traded on an exchange as a typical traded asset.

#### 1.2 Data Gathering

For the assignment, we downloaded monthly options on  $Amazon\ Inc.$  (ticker: AMZN) and  $S&P\ 500\ ETF$  (ticker: SPY) at various strike prices for the following dates:

- 02/15/19 Friday, February 15 2019;
- 03/15/19 Friday, March 15 2019;
- 04/18/19 Thursday, April 18 2019.

A wide variety of option strike prices were considered, with the following ranges:

- AMZN \$1555 to \$1725 in increments of \$5 (35 strike prices);
- SPY \$256 to \$284 in increments of \$1 (29 strike prices).

Intra-day minute closing price data was gathered for both put and call options with expiration dates and strike prices detailed above. This intra-day data was gathered for the trading day 2/6/19 (February 6 2019; **DATA1**). Additionally, intra-day minute closing price data was also downloaded for each of the underlying assets. This data was downloaded for both 2/6/19 (February 6 2019; **DATA1**), and 2/7/19 (February 7 2019; **DATA2**).

<sup>3.</sup> State Street Global Advisors 2019

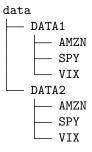

<sup>4.</sup> CBOE (Chicago Board Options Exchange) 2019

This data detailed above was gathered utilizing  $Rblpapi^5$ , which provides an R interface to data on the Bloomberg Terminal<sup>6</sup>. The data download was automated, and corresponding intra-day prices for each of the options were output to individual files. The source code for this implementation is available in Appendix D.1.1.

Furthermore, as a proxy for the *risk-free rate*, we chose to utilize the effective Federal Funds Rate (FFR). This is the interest rate at which depository institutions in the United States lend reserve balances to other depository institutions overnight. This data was gathered for both dates, and correspond to **DATA1** and **DATA2**. The effective FFR is published daily by the US Federal Reserve Board of Governors, and are expressed as yields per annum.<sup>7</sup>

#### 1.2.1 Data Cleaning

For easier programmatic access, the data was placed in a hierarchical structure, corresponding to the **DATA1**, **DATA2** data division. Each of the option and asset prices for the corresponding days were placed in the requisite sub-folders. This directory structure is reproduced below.

#### 8 directories

Option price filenames were changed to OOC format option names, discussed further below. This was done utilizing a cleaning script, written in Python. This script employs utility functions from the fe621 Python package<sup>8</sup>.

## 1.3 Option Naming Convention

A modern convention for naming option contracts was proposed by the Options Clearing Commission (OCC) in 2008<sup>9</sup>, and adopted in 2010. The OCC is an organization that acts as both the issuer and guarantor for option and future contracts. The OCC is governed by the Securities and Exchange Commission (SEC) and the Commodities Futures Trading Commission (CFTC). The current convention for option naming is best explained by example.

Consider the option code, AMZN190215C01960000. This corresponds to a Call Option on Amazon Inc. (AMZN), with a strike price of \$1960.00 and an expiration date of 2/15/19 (February 15 2019). The methodology of this nomenclature is explained in detail below:

5. Armstrong et al. 2018

<sup>6.</sup> Bloomberg L.P. 2019

<sup>7.</sup> Board of Governors of the Federal Reserve System 2019

<sup>8.</sup> Weerawarana 2019

<sup>9.</sup> Options Symbology Initiative Working Group 2008

## AMZN190215C01960000

- AMZN Ticker of the company (arbitrary length; always first sequence of characters)
- 19 Expiration year of the contract (shortened to two digits, i.e.  $2019 \rightarrow 19$ )
- 02 Expiration month of the contract
- 15 Expiration day of the contract
- C Type of option (C for call, P for put)
- 01960 Dollar component of strike price (in \$; always 5 digits)
- $\bullet$ 000  $\frac{1}{1000}^{\rm th}$  Dollar component of strike price (in  $\frac{1}{1000}\$;$  always 3 digits)

Similarly, the following option code corresponds to a Put Option on SPDR S&P 500 ETF (SPY), with a strike price of \$287.50 and an expiration date of 3/15/19 (March 15 2019):

#### SPY190315P00287500

Finally, the following option code corresponds to a Call Option on CBOE Volatility Index (VIX), with a strike price of \$16.35 and an expiration date of 4/18/19 (February 18 2019):

#### VIX190418C00016350

## 2 Data Analysis

Note: All Python scripts reproduced in this section are extracted from the fe621<sup>10</sup> package created for this class.

## 2.1 Black-Scholes Model

With the probabilities  $d_1$  and  $d_2$  defined as:

$$d_1 = \frac{\log\left(\frac{S_t}{K}\right) + \left(r + \frac{\sigma^2}{2}\right)(T - t)}{\sigma\sqrt{T - t}}$$
$$d_2 = d_1 - \sigma\sqrt{T - t}$$
$$\Phi(x) = \int_{-\infty}^x \phi(z)dz = \int_{-\infty}^x \frac{1}{\sqrt{2\pi}}e^{\frac{-z^2}{2}}dz$$

```
from typing import Tuple
  import numpy as np
  def computeD1D2(current: float, volatility: float, ttm: float, strike: float,
                   rf: float) -> Tuple[float, float]:
       """Helper function to compute the risk-adjusted priors of exercising the
8
9
      option contract, and keeping the underlying asset. This is used in the
10
       computation of both the Call and Put options in the
      Black-Scholes-Merton framework.
11
12
13
       Arguments:
14
           current {float} -- Current price of the underlying asset.
           volatility {float} -- Volatility of the underlying asset price.
15
           ttm {float} -- Time to expiration (in years).
16
           strike \{float\} -- Strike price of the option contract.
17
18
           rf {float} -- Risk-free rate (annual).
19
20
      Returns:
21
          Tuple[float, float] -- Tuple with d1, and d2 respectively.
22
23
      d1 = (np.log(current / strike) + (rf + ((volatility ** 2) / 2)) * ttm) \
24
          / (volatility * np.sqrt(ttm))
25
26
      d2 = d1 - (volatility * np.sqrt(ttm))
27
      return (d1, d2)
```

../fe621/black\_scholes/util.py

<sup>10.</sup> Weerawarana 2019

*Note:* The following assumes the dividend rate, q = 0.

#### 2.1.1 Put Option

The Black-Scholes Option price for a European Put  $(P(S_t))$  option is defined as:

$$P(S_t) = Ke^{-r(T-t)}\Phi(-d_2) - S_t\Phi(-d_1)$$

```
from .util import computeD1D2
3
  from scipy.stats import norm
  import numpy as np
  def blackScholesPut(current: float, volatility: float, ttm: float,
8
                       strike: float, rf: float) -> float:
      """Function to compute the Black-Scholes-Merton price of a European Put
10
      Option, parameterized by the current underlying asset price, volatility,
      time to expiration, strike price, and risk-free rate.
11
12
13
      Arguments:
14
           current {float} -- Current price of the underlying asset.
           volatility {float} -- Volatility of the underlying asset price.
15
           ttm {float} -- Time to expiration (in years).
16
17
           strike {float} -- Strike price of the option contract.
           rf {float} -- Risk-free rate (annual).
18
19
20
      Returns:
      float -- Price of a European Put Option contract.
21
22
23
24
      d1, d2 = computeD1D2(current, volatility, ttm, strike, rf)
25
26
      put = (strike * np.exp(-1 * rf * ttm) * norm.cdf(-1 * d2)) \setminus
           - (strike * norm.cdf(-1 * d1))
27
28
       return put
```

../fe621/black\_scholes/put.py

#### 2.1.2 Call Option

The Black-Scholes Option price for a European Call  $(C(S_t))$  option is defined as:

$$C(S_t) = S_t \Phi(d_1) - Ke^{-r(T-t)} \Phi(d_2)$$

```
10
      Option, parameterized by the current underlying asset price, volatility,
11
       time to expiration, strike price, and risk-free rate.
12
13
       Arguments:
           current {float} -- Current price of the underlying asset.
14
           volatility {float} -- Volatility of the underlying asset price.
15
           ttm {float} -- Time to expiration (in years).
16
           strike {float} -- Strike price of the option contract.
17
18
           rf {float} -- Risk-free rate (annual).
19
20
       Returns:
       float -- Price of a European Call Option contract.
21
22
23
24
      d1, d2 = computeD1D2(current, volatility, ttm, strike, rf)
25
      call = (current * norm.cdf(d1)) \
26
           - (strike * np.exp(-1 * rf * ttm) * norm.cdf(d2))
27
28
29
      return call
```

../fe621/black\_scholes/call.py

## 2.1.3 Put-Call Parity

The relationship between the price of a Call and Put option is governed by Put-Call parity:

$$P(S_t) = C(S_t) - S_t + Ke^{-r(T-t)}$$

```
import numpy as np
  def call(put: float, current: float, strike: float, ttm: float,
4
5
           rf: float) -> float:
       """Function to compute the price of a European Call option contract from a
6
      European Put option contract price using Put-Call parity.
8
9
      Arguments:
           put {float} -- Price of the put option.
10
           current {float} -- Current price of the underlying asset.
12
           strike {float} -- Strike price of the option contract.
           ttm {float} -- Time to expiration (in years).
13
           rf {float} -- Risk-free rate (annual).
14
15
16
      Returns:
17
          float -- Price of a European Call Option contract.
18
19
      return put + current - (strike * np.exp(-1 * rf * ttm))
20
21
22
23
  def put(call: float, current: float, strike: float, ttm: float,
24
          rf: float) -> float:
       """Function to compute the price of a European Put option contract from a
25
26
      European Call option contract price using Put-Call parity.
27
28
       Arguments:
29
           call {float} -- Price of the call option.
30
           current {float} -- Current price of the underlying asset.
```

../fe621/black\_scholes/parity.py

#### 2.1.4 The Greeks

The Greeks are the quantities representing the sensitivity of the price of a derivative with respect to changes in the underlying parameters. The following formulas are implemented to calculate each of the Greeks using the Black-Scholes option pricing formula. These formulas are derived in full in (Stefanica 2011) and (Weerawarana 2016).

*Note:* The following assumes the dividend rate, q = 0.

#### Delta

The Delta ( $\Delta$ ) of an option is the first derivative of an option with respect to the price of the underlying asset at time t,  $S_t$ .

$$\Delta(C) = \frac{\partial C(S_t)}{\partial S_t} = \Phi(d_1)$$

## Gamma

The Gamma ( $\Gamma$ ) of an option is the second derivative of an option with respect to the price of the underlying asset at time t,  $S_t$ .

$$\Gamma(C) = \frac{\partial^2 C(S_t)}{\partial S_t^2} = \frac{\phi(d_1)}{S_t \sigma \sqrt{T - t}}$$

#### Vega

The Vega  $(\nu)$  of an option is the first derivative of an option with respect to the volatility of the underlying asset at time t,  $\sigma$ .

$$\nu(C) = \nu(P) = \frac{\partial C(S_t)}{\partial \sigma} = S_t \sqrt{T - t} \, \phi(d_1)$$

```
11

## 2.2 Numeric Optimization

#### 2.2.1 Bisection Method

In this section, we implement the Bisection optimization method. The bisection algorithm is outlined in Algorithm 1. The algorithm is implemented recursively.

## **Algorithm 1:** Bisection Algorithm

```
Input: Input function, f to be optimized; must have sign change. Search space start and stop points, a and b. Tolerance level, \epsilon.

Output: Point x^* \in [a,b] where f(x^*) = 0.

Let midpoint = m;

repeat

m = \frac{a+b}{2};

if f(a) \times f(mid) < 0 then
b = m

end

if f(b) \times f(mid) < 0 then
a = m

end

until (b-a) < \epsilon;

return \frac{a+b}{2};
```

```
from typing import Callable
  import numpy as np
  def bisectionSolver(f: Callable, a: float, b: float,
5
6
                       tol: float=10e-6) -> float:
       """Bisection method solver, implemented using recursion.
8
9
       Arguments:
           f {Callable} -- Function to be optimized.
10
           a {float} -- Lower bound.
11
12
           b {float} -- Upper bound.
13
       Keyword Arguments:
14
           tol {float} -- Solution tolerance (default: {10e-6}).
15
16
17
           Exception -- Raised if no solution is found.
18
19

25
26
27
       # Check if estimate is within tolerance
       if (b - a) < tol:
28
29
           return mid
30
31
       # Evaluate function at midpoint
       f_mid = f(mid)
```

```
# Check position of estimate, move point and re-evaluate
if (f(a) * f_mid) < 0:
    return bisectionSolver(f=f, a=a, b=mid)
elif (f(b) * f_mid) < 0:
    return bisectionSolver(f=f, a=mid, b=b)
else:
    raise Exception("No solution found.")
```

../fe621/optimization/bisection.py

#### 2.2.2 Newton Method

In this section, we implement the Newton optimization method. The Newton method algorithm is outlined in Algorithm 2.<sup>11</sup> The algorithm is implemented recursively.

## Algorithm 2: Newton's Method

```
Input: A differentiable function f: \mathbb{R}^a \to \mathbb{R}^b \, \forall \, a,b \in \mathbb{N}_{>0}. Starting guess for the root x_0. Tolerance level, \epsilon.

Output: x^* \in \mathbb{R}^a, such that f(x^*) = 0
k = 1;

repeat
x_{k+1} = x_k - \frac{f(x_k)}{f'(x_k)};
k = k+1
until |x_k - x_{k-1}| < \epsilon;

return x_{k+1};
```

```
from typing import Callable
  import numpy as np
  def newtonSolver(f: Callable, f_prime: Callable, guess: float,
6
                    tol: float=10e-6, prev: float=0) -> float:
7
       """Newton method solver for 1 dimension, implemented recursively.
8

#### 2.2.3 Convergence Comparison

Here, we compare the performance of each of the optimization methods described above, the Bisection method and Newton method. This was done by computing the average daily implied volatility on the complete SPY option chain in the dataset.

The average daily implied volatility is computed by first calculating the implied volatility by-minute. Then, the mean of these minute-level implied volatilities is computed and is treated as the average daily implied volatility of the given option. For this comparison, the tolerance level of each of the termination conditions was set to  $1 \times 10^{-4}$ .

|                                  | Newton Method      | Bisection Method   |
|----------------------------------|--------------------|--------------------|
| Number of Input Options          | 165.0              | 165.0              |
| Number of Output Options         | 164.0              | 164.0              |
| Number of Dropped Options        | 1.0                | 1.0                |
| Time Elapsed for Computation (s) | 2423.1484701633453 | 2406.0394039154053 |
| Average Time per Option (s)      | 14.685748304020274 | 14.582056993426699 |

**Table 1:** Convergence comparison of average daily implied volatility computation on the SPY option chain using the Bisection and Newton optimization methods.

The time elapsed for these computations, and other related statistics under each of the two optimization methods are presented in Table 1.

Despite having a theoretical quadratic convergence rate, Newton's method results in slower performance compared to the Bisection method. This is evident from both the total time elapsed, and the average time per operation (computed to include dropped option computations for consistency).

This can be attributed to the fact that some of the minute-level implied volatility optimizations do not have solutions. The Bisection method reaches a state of "no solution" faster than Newton's method, as it employs a technique of reducing the possible range of the solution. This converging search space would suggest it discovers a state of "no solution" faster than the unbounded search space of the Newton method. In principle - on the condition that the existence of a solution is guaranteed - the Newton method will converge faster than the Bisection method, given a reasonable initial guess.

## 2.3 Implied Volatility

In this section, we utilize the functions and data described above to calculate the average implied volatility of each of the option chains. This was done for the entire dataset using the Bisection Method. Additionally, we also discuss the differences in average daily implied volatility between *in-the-money* and *out-of-the-money* options.

### 2.3.1 Average Daily Implied Volatility

Average daily implied volatility was computed for each option, across all strike prices and expiration dates, for both SPY and AMZN option chains. This optimization on the aggregate dataset was completed using the Bisection Method.

This was done by first computing the implied volatility for each minute, solving for some  $\sigma$  such that  $(C(S_t)|_{\sigma} - P = 0)$  or  $(P(S_t)|_{\sigma} - P = 0)$  for a call or put option respectively. Then, the mean of each of these implied volatilities was computed to obtain the daily average implied volatility for an option with a given strike price and expiration date. For this comparison, the tolerance level of each of the termination conditions was set to  $1 \times 10^{-7}$ .

The complete dataset of average daily implied volatility is reproduced for the complete option chains on SPY in Appendix A.1 and AMZN in Appendix A.2.

## 2.4 Implied Volatility Analysis

We also compared the average daily implied volatility of options in-the-money, and out-of-the-money. For this comparison, we defined the ratio of money-ness to be  $\pm 5\%$  of the current underlying asset price, where options within the range are in-the-money, and out-of-the-money otherwise. This comparison data is presented in Table 2.

|  | SPY                 | AMZN                |
|--|---------------------|---------------------|
| In-the-money Options Average Daily Implied Vol     | 0.15739310934145576 | 0.29781477676343643 |
| Out-of-the-money Options Average Daily Implied Vol | 0.16631389625540363 | 0.3189350623328305  |

**Table 2:** Comparison of *in-the-money* and *out-of-the-money* options through the lens of their average daily implied volatility.

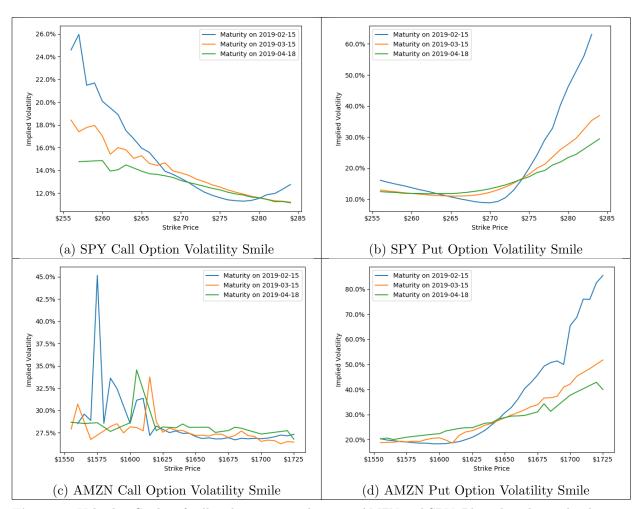

## 2.5 Volatility Plots

In this section, we explore the visual relationship between the computed average daily implied volatility (see Section 2.3.1), the strike price, and the expiration date of the options. The source code for this question is reproduced in Appendix D.2.4.

#### 2.5.1 Volatility Smile

The Volatility Smile is the graph of the relationship between the strike price and the average daily implied volatility of the option:

$$\hat{\sigma} = \hat{f}(K)$$

**Figure 1:** Volatility Smiles of call and put option chains on AMZN and SPY. Plots the relationship between the strike price and implied volatility for various maturities.

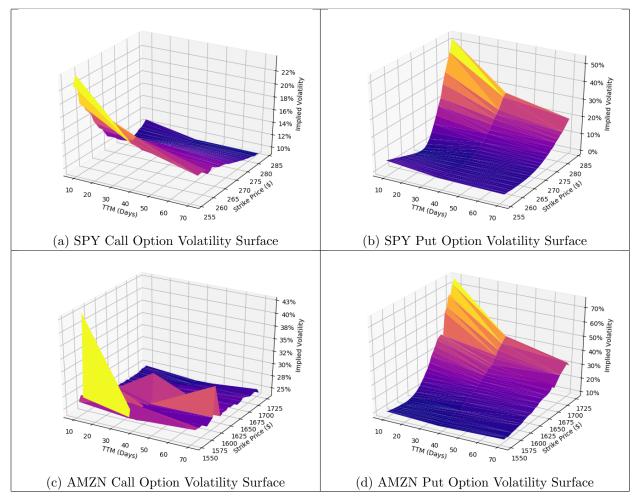

The various options (of the same type and underlying asset) are graphed on the same axes, and different expiration dates are displayed in different colors. The Volatility Smile is plotted for both put and call options on both SPY and AMZN in Figure 1.

## 2.5.2 Volatility Surface

The Volatility Surface is the graph of the relationship between the strike price, the time to maturity, and the average daily implied volatility of the option:

$$\hat{\sigma} = \hat{f}(K, \sqrt{T - t})$$

The various options (of the same type and underlying asset) are graphed on the same axes. The Volatility Surface is plotted for both put and call options on both SPY and AMZN in Figure 2.

**Figure 2:** Volatility Surfaces of call and put option chains on AMZN and SPY. Plots the relationship between the strike price, time to maturity, and the implied volatility.

## 2.6 The Greeks

In this section, we compute the Greeks for the options. To do this, we employ the estimate of the average daily implied volatility (see Section 2.3.1). We compute the Greeks using both the analytical formula (see Section 2.1.4), and by estimation of the derivatives using the central finite difference Method.

#### 2.6.1 Central Finite Difference Method

The central finite difference method is a framework for computing the numerical derivative of a three times differentiable function in an interval around the point a, f. Then, numerical approximations for the first and second derivatives are  $^{12}$ :

Let 
$$h > 0$$
 
$$f'(a) \approx \frac{f(a+h) - f(a-h)}{2h} + O(h^2)$$
 
$$f''(a) \approx \frac{f(a+h) - 2f(a) + f(a-h)}{h^2} + O(h^2)$$

## 2.6.2 Analytical and Estimated Greeks

The analytical and estimated Delta,  $\Delta$ , Gamma,  $\Gamma$ , and Vega,  $\nu$ , for the complete SPY and AMZN option chains are presented in Appendix B.1 and Appendix B.2, respectively. The source code for this computation is reproduced in Appendix D.2.5.

## 2.7 DATA2 Computed Prices

Finally, we compute option prices utilizing the closing price data for DATA2. This was accomplished using the risk-free rate for DATA2, and correspondingly computed time-to-maturities. The computed prices are presented for both the SPY and AMZN option chains in Appendix C.1 and Appendix C.1, respectively. The source code for this computation is reproduced in Appendix D.2.6.

## 3 Numerical Integration

## 3.1 Quadrature Methods

In this section, we implement the Trapezoidal Rule and Simpson's Rule quadrature methods.

$$\label{eq:left_left} \text{Let data} = \boldsymbol{x}$$
 Let  $i^{\text{th}}$  element of  $\boldsymbol{x} = x_i$ 

#### 3.1.1 Trapezoidal Rule

Let Trapezoidal rule approximation =  $T_N(f)$ 

$$\Rightarrow T_N(f) = \sum_{i=1}^N \left[ \left( \frac{f(x_{i-1}) + f(x_i)}{2} \right) \times h \right]$$

$$\Rightarrow h \times \sum_{i=1}^N \left[ \frac{f(x_{i-1}) + f(x_i)}{2} \right] = h \times \left( \frac{1}{2} f(x_0) + f(x_1) + \dots + f(x_{N-1} + \frac{1}{2} f(x_N)) \right)$$

$$\therefore T_N(f) = h f(\mathbf{x}) - \frac{h}{2} (f(x_0) + f(x_N))$$

```
from typing import Callable
   import numpy as np
  def trapezoidalRule(f: Callable, N: float, start: float=-1e6,
                      stop: float=1e6) -> float:
       """Function to approximate the numeric integral of a function, f, using
8
      the Trapezoidal rule.
9
10
      Arguments:
           f {Callable} -- Function who's integral is to be estimated.
12
           N {int} -- Number of nodes to consider.
13
14
      Keyword Arguments:
           start {float} -- Starting point (default: {-1e6}).
15
           stop {float} -- Stopping point (default: {1e6}).
16
17
18
           float -- Approximation of the area under the function.
19
20
21
22
      # Building values for approximation, and getting step size
23
      x, h = np.linspace(start=start, stop=stop, num=N, retstep=True)
24
25
      # Estimating area using trapezoidal rule, return
       return np.sum((h * f(x))) - ((h / 2) * (f(start) + f(stop)))
```

../fe621/numerical\_integration/trapezoidal.py

#### 3.1.2 Simpson's Rule

The following equation is derived in full in (Florescu 2019).

Let Simpson's rule approximation =  $S_N(f)$  $\Rightarrow S_N(f) \approx \frac{h}{6} \times \sum_{i=1}^N \left[ f(x_{i-1}) + 4f\left(\frac{x_{i-1} + x_i}{2}\right) + f(x_i) \right]$   $= \frac{h}{6} \left( \sum_{i=1}^N [f(x_{i-1}) + f(x_i)] + 4 \times \sum_{i=1}^N \left[ f\left(\frac{x_{i-1} + x_i}{2}\right) \right] \right)$ 

Note that  $\left(\frac{x_{i-1}+x_i}{2}\right)$  is the midpoint between the points in  $\boldsymbol{x}$ . Let the above  $=\boldsymbol{x}_{\mathrm{mid}}$ 

$$\therefore S_N(f) \approx \frac{h}{6} \left( 2f(\boldsymbol{x}) - (f(x_0) + f(x_N)) + 4f(\boldsymbol{x}_{\text{mid}}) \right)$$

```
from typing import Callable
   import numpy as np
  def simpsonsRule(f: Callable, N: float, start: float=-1e6,
                    stop: float=1e6) -> float:
       """Function to approximate the numeric integral of a function, f, using
8
       Simpson's rule.

33
       return area
34
```

../fe621/numerical\_integration/simpsons.py

## 3.2 Truncation Error Analysis

To examine the behavior of each of the quadrature methods described above, we approximate the integral of the following function:

$$f(x) = \begin{cases} \frac{\sin(x)}{x}, & \text{for } x \neq 0, \\ 1, & \text{for } x = 0. \end{cases}$$

We parameterize the start and stop points of the quadrature methods with a variable a, such that start = -a and stop = a. Furthermore, we define the number of segments with variable N.

Let approximation with parameters a and  $N = I_{N,a}$ 

It is know analytically that the value of the integral  $\int_{\infty}^{\infty} f(x)dx = \pi$ . We evaluate the performance of each of the quadrature methods with various values of a and N. Then, we compute the *truncation error* of the approximation, defined as:

Truncation error for approximation with parameters a and  $N = |I_{N,a} - \pi|$ 

|             | N = 1000       | N = 10000       | N = 100000     | N = 1000000    | N = 10000000   |
|-------------|----------------|-----------------|----------------|----------------|----------------|
| a = 100     | 1.70837393e-02 | 7.23666391e-04  | 6.28030676e+00 | 6.28753820e+00 | 8.02007982e-04 |

**Table 4:** Simpsons quadrature rule truncation error for varying values of a and N.

Table 3 and Table 4 report the truncation error for the Trapezoidal and Simpson's quadrature rules, respectively. The script used to produce this table is reproduced in Appendix D.3.1. Variations of N and a are explores in increasing powers of 10, with a progressing from 100 to 1,000,000, and N from 1,000 to 10,000,000.

It is evident from Table 3 that the Trapezoidal quadrature rule performs relatively well across all values of a, even at relatively low values of N. Compared to Simpson's quadrature rule truncation error (Table 4), the Trapezoidal quadrature rule also performs relatively better with larger values of N, and small values of a.

A potential explanation of this may be the interpolating behavior of the Simpson's quadrature rule. The function  $\frac{\sin(x)}{x}$  is significantly more linear than quadratic in small intervals, and thus the quadratic

interpolating behavior of the Simpson's quadrature rule is a poor approximation heuristic for the function with low values of a.

Finally, it can be observed that both quadrature rule approximations converge commensurately as the values of a and N increase. However, it is clear that the Trapezoidal quadrature rule approximation converges at a faster rate than the Simpson's quadrature rule approximation with increasing values of a and N.

## 3.3 Convergence Analysis

Typically, the true value of the objective integral is unknown. In this case, we would evaluate the rate of change of the objective function (i.e. convergence) computation with respect to the number of segments, N. We assign an arbitrary convergence criteria,  $\epsilon$  to test the convergence with progressively increasing (in powers of 10) values of N.

```
Let approximation with parameter N = I_N
Repeat while: |I_N - I_{N_{\text{old}}}| > \epsilon
```

We evaluate the number of iterations required for a convergence level of  $\epsilon = 10^{-3}$  for the Trapezoidal and Simpson's quadrature rules. The output of this evaluation is reproduced in Table 5. The solution source code for this analysis is reproduced in Appendix D.3.2. The fe-621 package<sup>13</sup> sub-module used in this analysis is presented below.

```
from typing import Callable, Tuple
  import numpy as np
  def convergenceApproximation(f: Callable, rule: Callable, epsilon: float=1e-3,
                                 start: float=-1e6, stop: float=1e6) \
                                -> Tuple[float, int]:
8
       """Function to approximate the numeric integral of a function, f, using
9
       a given quadrature rule and a tolerance level epsilon.
11
12
           f {Callable} -- Function for which the integral is to be estimated.
13
           rule {Callable} -- Function to be used to approximate area. Must take
14
                               positional arguments f, N, start and stop.
15
16
      Keyword Arguments:
           epsilon {float} -- Tolerance level (default: {1e-3}).
17
18
           start {float} -- Starting point (default: {-1e6})
           stop {float} -- Stopping point (default: {1e6}).
19
20
21
      Returns:
22
           Tuple[float, int] -- Approximation of the area under the function
23
                                 and the number of segments (area, segments).
24
25
26
      # Flags
27
       area_old = 0
28
       area_new = 1
29
30
       while (np.abs(area_new - area_old) > epsilon):
31
32
           # Set new area to old area
33
           area_old = area_new
```

13. Weerawarana 2019

```
34
35
           # Increase N by powers of 10
36
37
           # Computing area with given parameters
38
39
           area_new = rule(f=f, N=N, start=start, stop=stop)
40
41
           print('On iteration {0} method {1} convergence {2} val {3}'.format(
42
43
               '{:.5e}'.format(np.abs(area_new - area_old)),
44
45
               area_new))
46
47
       # Return final area and number of segments
       return (area_new, N)
```

../fe621/numerical\_integration/convergence.py

|                  | Estimated Area | Segments       |
|------------------|----------------|----------------|
| Trapezoidal Rule | 3.14162154e+00 | 1.00000000e+05 |
| Simpson's Rule   | 3.14159078e+00 | 1.00000000e+07 |

**Table 5:** Analysis of segments required for convergence under the Trapezoidal and Simpson's quadrature rules.

Analyzing the results in Table 5, it is evident that the number of segments required for convergence under the Trapezoidal quadrature rule is significantly less than that required under Simpson's quadrature rule. This difference is significant, with the Trapezoidal quadrature rule requiring segments two orders of magnitude less than Simpson's quadrature rule for convergence. These behavior is in agreement with the previous analysis of convergence with respect to varying values of N and a, explored in Section 3.2.

## 3.3.1 Arbitrary Function

Additionally, we also evaluate each quadrature rule with respect to the number of segments required for convergence with an additional arbitrary integral:

$$g(x) = 1 + e^{-x^2} \cos(8x^{\frac{2}{3}})$$
$$\int_0^2 g(x) dx$$

|                  | Estimated Area | Segments        |
|------------------|----------------|-----------------|
| Trapezoidal Rule | 1.95879798e+00 | 1.000000000e+04 |
| Simpson's Rule   | 1.95879793e+00 | 1.00000000e+03  |

**Table 6:** Analysis of segments required for convergence of an arbitrary integral under the Trapezoidal and Simpson's quadrature rules.

The estimates and segments required for convergence for the integral  $\int_0^2 g(x) dx$  are presented in Table 6. The source code for this analysis is reproduced in Appendix D.3.3.

### D Solution Source Code

### D.1 Question 1 Implementation

#### D.1.1 Bloomberg Terminal Data Download

```
library("Rblpapi")
  # Connect to Bloomberg Terminal backend service
  blpConnect(host = "localhost", port = 8194)
7
  #-----
8
   # Data Download Functionality
10
11
  getPrice <- function(security, startTime, endTime, timeZone) {</pre>
12
13
    # Downloads and returns the closing price of a given security
    # for each minute in the trading day.
14
15
16
    # Args:
17
        security: Name of the security to be downloaded.
18
         startTime: Datetime object with the start time.
        endTime: Datetime object with the end time.
19
20
        timeZone: Time zone of the target start and end times.
21
22
    # Returns:
23
        DataFrame with the closing price for each minute in the
        trading day.
24
25
26
     # Getting price data
27
     data <- getBars(security = security, barInterval = 1,</pre>
28
                     startTime = startTime, endTime = endTime,
29
                     tz = timeZone)
30
     # Isolate time and closing price
31
